MOBILE PHASE GRADIENT GENERATION MICROFLUIDIC DEVICE

TECHNICAL FIELD

The present invention generally relates to microfluidic devices that employ a mobile phase containing differing concentrations of a selected mobile-phase component. In particular, the invention relates to microfluidic devices that separate a fluid sample into its constituent components, wherein the employed mobile phase exhibits a concentration gradient of a selected mobile-phase component. In addition, the invention relates to the use of microfluidic devices to generate a gradient or differing concentrations of a selected mobile-phase component within a small volume of mobile phase in order to separate the components of a fluid sample.

BACKGROUND

Microfluidic device technologies, also referred to as lab-on-a-chip technologies, have been proposed for a number of different applications in various fields. In the field of biology, for example, microfluidic devices may be used to carry out cellular assays. In addition, microfluidic devices have been proposed to carry out separation techniques in the field of analytical chemistry.

Generally, microfluidic devices may be used to separate the components of a fluid sample using either of two techniques: capillary electrophoresis or chromatography. Capillary electrophoresis involves the separation of molecules based on differences in the electrophoretic mobility of the molecules. Typically, microfluidic devices employ a controlled application of an electric field to induce fluid flow and/or to provide flow switching. In order to effect reproducible and/or high-resolution separation, a fluid sample "plug" (a predetermined volume of fluid sample) must be controllably injected

100-0924-1

10

15

20

25

into a capillary separation column or conduit. For fluid samples containing high molecular weight charged biomolecular analytes, such as DNA fragments and proteins, microfluidic devices containing a capillary electrophoresis separation conduit that is a few centimeters in length may be effectively used to carry out separation of small sample 5 plugs having a length on the order of micrometers. Once injected, high sensitivity detection, such as laser-induced fluorescence, may be employed to resolve a separated fluorescent-labeled sample component.

For samples containing analyte molecules with low electrophoretic mobility differences, such as those containing small drug molecules, the separation technology of choice is generally chromatography. Chromatographic separation occurs when a mobile phase carries sample molecules through a chromatography bed (stationary phase) where sample molecules interact with the stationary phase surface. The velocity at which a particular sample component travels through a chromatography bed depends on the component's partition between mobile phase and stationary phase. Microfluidic devices that incorporate a liquid chromatographic functionality have been described in U.S. Serial 10 No. 09/908,231. These microfluidic devices may employ integrated mechanical valve 15 technologies, such as those described in U.S. Serial No. 09/908,292, for sample introduction and to reduce the volume of "dead space" in the microfluidic devices.

There are many chromatographic techniques known in the art. See e.g., Kutter et al. (1998), "Solvent-programmed microchip open-channel electrochromatography," *Anal. Chem.* 70:3291-3297. For example, in reverse phase liquid chromatography, where the stationary phase offers a hydrophobic surface and the mobile phase is usually a mixture of water and an organic solvent, the least hydrophobic component moves through the chromatography bed first, followed by other components, in order of increasing hydrophobicity. In other words, the chromatographic separation of sample components 20 may be based on hydrophobicity.

In isocratic liquid chromatography, the content of the mobile phase is constant throughout the separation. Gradient liquid chromatography, on the other hand, requires the content of the mobile phase to change during separation. Gradient liquid 25 chromatography not only offers high resolution and high-speed separation of wide ranges

of compounds, it also allows injection of large sample volumes without compromising separation efficiency. During the initial period when the sample is introduced, the mobile phase strength is often kept low, and the sample is trapped at the head of the liquid chromatography column bed. As a result, interfering moieties, such as salts, are washed away. In this regard, gradient liquid chromatography is suited to analyze fluid samples containing a low concentration of analyte moieties.

Typically, pressurizing means are employed to provide flow through packed columns in liquid chromatography. Such pressurizing means typically include pumps that are designed for optimal performance at a certain flow rate range, generally between about 50 μ L/min to about 1 mL/min. To generate a gradient of a selected mobile-phase component within a mobile phase, two pumps may be employed to pump two fluids, each fluid containing a different concentration of the selected mobile-phase component. The fluids are mixed to form the mobile phase and introduced into the column. By varying the relative flow rate of the pumps, a concentration gradient of the selected mobile-phase component may be formed within the mobile phase flowing through the column. However, the quality of the gradient generated by this technique is limited by the performance of the pumps. In some cases, a gradient may require a fluid flow rate that lies outside the capability of the pumps. This limitation is particularly pronounced when microbore liquid chromatography columns are employed, because the required mobile-phase flow rate through the columns is extremely low.

Use of conventional chromatographic equipment with microfluidic devices for separating the components of a fluid may present other technical problems. For example, in order to obtain a smooth gradient, conventional liquid chromatography systems employ a pressure damper as well as a mixer. The pressure damper and the mixer require a certain volume of fluid for proper operation. This volume is associated with a delay time, i.e., the time it takes for a mobile phase to reach the liquid chromatography column after mixing. The delay time can be calculated as the quotient of the delay volume over the flow rate. For example, the combined volume of the damper and the mixer in a conventional liquid chromatography system is about 0.3 mL to about 0.5 mL. This translates to a delay time of about 0.3 minutes to about 0.5 minutes at a flow rate of 1

mL/min. However, if a microfluidic device is constructed for operation at a flow rate of less than about 1 μ L/min, the delay time increases to about 300 minutes to about 500 minutes. Such a long delay time renders microfluidic device-based gradient liquid chromatography impractical.

To overcome this limitation, commercial low flow rate liquid chromatography pumps typically employ a split flow design. In this design, pumps move mobile phase at a high flow rate, but only a portion of the mobile phase is delivered to the separation column. The remainder of the mobile phase is diverted into a waste stream. This adds to the cost of operation because typically less than 1% of the mobile phase is actually used for separation.

In addition, the concentration of the selected mobile-phase components delivered to the column changes as gradient liquid chromatography is carried out. In most cases, the viscosity of the mobile phase also changes. This tends to change the pressure profile within the column. To compensate for such pressure profile changes, an electronic flow control unit that includes a flow meter and a variable flow resistor is used to control commercial chromatography pumps. As mobile phase is delivered to the column, the flow meter measures the flow rate of the mobile phase to provide feedback control over the variable flow resistor. Nevertheless, current flow sensor technologies are incapable of accurately measuring flow rates of less than 1 μ L/min, especially in gradient mode, and are therefore unsuitable for use in microfluidic devices that are employed in gradient chromatography.

Thus, there is a need for integrated microfluidic device technology that allows control and generation of a gradient of a selected mobile-phase component within a small volume of mobile phase in order to separate the components of a fluid sample. In particular, there is a need for an improved microfluidic device that employs a smooth gradient at low flow rates, especially in flow rate ranges of less than 1 μ L/min.

SUMMARY OF THE INVENTION

In a first embodiment, the invention relates to a microfluidic device for separating the components of a fluid sample. The microfluidic device comprises a substrate having

a microchannel formed in a surface thereof and a cover plate arranged over the substrate surface. The cover plate, in combination with the microchannel, defines a separation conduit for separating the components of the fluid sample according to a specific component property. The microfluidic device also includes an integrated gradient-generation means for generating a gradient of a selected mobile-phase component in a mobile phase. The integrated gradient-generation means is arranged to allow the mobile phase from the gradient-generation means to be transported through an inlet port into the separation conduit and out of an outlet port. Typically, though not necessarily, the integrated gradient-generation means is formed at least in part within the substrate and/or in the cover plate.

In another embodiment, the invention relates to a microfluidic device that employs a gradient-generation means for generating a gradient of a selected mobile-phase component in a mobile phase in order to separate the components of the fluid sample. The gradient-generation means is formed from a substrate and a cover plate arranged over a surface of the substrate. A microchannel having an upstream terminus and a downstream terminus is formed in the surface of the substrate. The cover plate, in combination with the microchannel, forms a mobile-phase holding conduit having a length defined by the upstream terminus and the downstream terminus. A plurality of inlet ports is arranged along the length of the mobile-phase holding conduit, and an outlet port is located downstream from the inlet ports. A separation conduit is provided as well for separating the components of a fluid sample according to a specific component property, and a mobile-phase introducing means allows mobile phase from the mobile-phase holding conduit to flow through its outlet port and into a separation conduit.

In a further embodiment, the invention relates to a microfluidic device having an integrated mobile-phase source. The microfluidic device comprises a substrate having a microchannel formed in a surface thereof and a cover plate arranged over the substrate surface. The cover plate, in combination with the microchannel, defines a separation conduit for separating the components of the fluid sample according to a specific component property, and has an inlet port and an outlet port. An integrated mobile-phase source is provided comprising a microconduit having a length defined by an upstream

5

terminus and a downstream terminus. The microconduit contains a mobile phase that exhibits a gradient of a selected mobile-phase component along the length of the microconduit. The integrated mobile-phase source is arranged to allow the mobile phase to be transported through the inlet port into the separation conduit and out of the outlet port.

10

In a still further embodiment, the invention relates to a method for separating the components of a fluid sample. The method uses no more than about 100 μL of fluid to produce a mobile phase containing a gradient of the selected mobile-phase component. Preferably, no more than about 20 μL of fluid is used to produce the gradient-containing mobile phase. The gradient-containing mobile phase produced as a result is used to convey a fluid sample through the separation conduit, thereby separating the components of the fluid sample.

15

20

In another embodiment, the invention relates to a microfluidic device for producing a flow of mobile phase. The device comprises a mobile-phase source and a pressurizing means. The mobile-phase source comprises a mobile-phase holding microconduit having a length defined by an upstream terminus and a downstream terminus, and an outlet port located at the downstream terminus, and a mobile phase, contained in the mobile-phase holding microconduit, that exhibits differing concentrations of selected mobile-phase component along the length of the mobile-phase holding microconduit. The pressurizing means allows for the pressurization of the microconduit to force the mobile phase within the microconduit to flow toward the downstream terminus along the length of the microconduit and out the outlet port.

25

30

In still another embodiment, the invention relates to a microfluidic device for producing a flow of mobile phase. The microfluidic device comprises, a producing means for producing different concentrations of a selected mobile-phase component in different locations within a mobile phase comprising, a plurality of mobile-phase sources, a mobile-phase introducing means and a pressurizing means. The producing means comprises a mobile-phase-holding microconduit having a length defined by an upstream terminus and a downstream terminus, an outlet port located at the downstream terminus, and at least one inlet port in fluid communication with the mobile-phase holding

microconduit upstream from the outlet port. Each mobile-phase source contains a mobile phase of a different concentration of a selected mobile-phase component. The introduction means introduces plugs of mobile phase from the mobile-phase sources through the at least one inlet port into the mobile-phase holding conduit such that the 5 plugs are arranged in a predetermined order along the length of the mobile-phase holding conduit. The pressurizing means pressurizes the microconduit to force the mobile phase within the microconduit to flow toward the downstream terminus along the length of the microconduit and out the single outlet port.

Thus, the invention provides, in yet another embodiment, a method for producing 10 a flow of mobile phase. A mobile-phase source is provided comprising a mobile-phase-holding microconduit having a length defined by an upstream terminus and a downstream terminus, and an outlet port located at the downstream terminus, and a mobile phase, contained in the mobile-phase holding microconduit, that exhibits differing concentrations of selected mobile-phase component along the length of the microconduit. 15 The mobile-phase holding microconduit is pressurized to force the mobile phase within the mobile-phase holding microconduit to flow toward the downstream terminus along the length of the microconduit and out of the outlet port. Optionally, at least one inlet port is provided fluid communication with the mobile-phase holding microconduit, wherein the outlet port is located downstream from the at least one inlet port of the 20 mobile-phase holding microconduit. In such a case, a plurality of mobile-phase sources may be provided as well, each containing a mobile phase, wherein each mobile phase contains a different concentration of a selected mobile-phase component. Plugs of mobile phase from the mobile-phase sources are introduced through the at least one inlet port into the mobile-phase holding microconduit such that the plugs are arranged in a predetermined order along the length of the mobile-phase holding conduit. 25

For any of the embodiments, the mobile-phase holding microconduit may be defined or further defined by a substrate having a microchannel formed in a surface thereof in combination with a cover plate arranged over the substrate surface.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. 1A-1C, collectively referred to as FIG. 1, illustrate a version of the inventive microfluidic device having an integrated gradient-generation means. FIG. 1A illustrates the device in exploded view. FIGS. 1B and 1C schematically illustrate the microfluidic device in loading and operating configurations, respectively.

FIGS. 2A-2C, collectively referred to as FIG. 2, illustrate a version of the inventive microfluidic device similar to that illustrated in FIG. 1, but having a different integrated gradient-generation means. FIGS. 2A and 2B schematically illustrate the microfluidic device in loading configurations. FIG. 2C schematically illustrates the microfluidic device in an operating configuration.

FIG. 3 schematically illustrates a microfluidic device for separating the components of a fluid sample, wherein the microfluidic device contains a cascade of microchannels suitable for generating a smooth gradient in a mobile phase.

FIGS. 4A-4C, collectively referred to as FIG. 4, illustrate a switching structure employs rotational motion to controllably introduce, through a conduit, a plug of a first mobile phase followed by a second mobile phase. FIG. 4A illustrates the switching structure in exploded view. FIGS. 4B and 4C schematically illustrate the switching structure in first and second flow path configurations, respectively.

FIGS. 5A and 5B, collectively referred to as FIG. 5, illustrate a switching structure that employs rotational motion to controllably introduce, through a conduit, a plug of a first mobile phase, followed by a plug of a second mobile phase and the first mobile phase. FIG. 5A illustrates the switching structure in a first flow path configuration. FIG. 5B illustrate the switching structure in a second flow path configuration.

25

DETAILED DESCRIPTION OF THE INVENTION

Before the invention is described in detail, it is to be understood that, unless otherwise indicated, this invention is not limited to particular materials, components, or manufacturing processes, as such may vary. It is also to be understood that the

terminology used herein is for purposes of describing particular embodiments only, and is not intended to be limiting.

It must be noted that, as used in the specification and the appended claims, the singular forms "a," "an," and "the" include plural referents unless the context clearly dictates otherwise. Thus, for example, reference to "an inlet" includes a plurality of inlets, reference to "a fluid" includes a mixture of fluids, reference to "a cascade" includes a plurality of cascades, and the like.

In this specification and in the claims that follow, reference will be made to a number of terms that shall be defined to have the following meanings:

The term "fluid-tight" is used herein to describe the spatial relationship between two solid surfaces in physical contact such that fluid is prevented from flowing into the interface between the surfaces.

The term "fluid-transporting feature" as used herein refers to an arrangement of solid bodies or portions thereof that direct fluid flow. Fluid-transporting features include, but are not limited to, chambers, reservoirs, conduits, and channels. The term "conduit" as used herein refers to a three-dimensional enclosure formed by one or more walls and having an inlet opening and an outlet opening through which fluid may be transported. The term "channel" is used herein to refer to an open groove or a trench in a surface. A channel in combination with a solid piece over the channel forms a "conduit". A conduit may also be formed from a stencil interposed between two solid surfaces.

The term "microalignment means" is defined herein to refer to any means for ensuring the precise microalignment of microfabricated features in a microfluidic device. Microalignment means can be formed either by laser ablation or by other methods well known in the art that are used to fabricate shaped pieces. Representative microalignment means that can be employed herein include a plurality of appropriately arranged protrusions in component parts, e.g., projections, depressions, grooves, ridges, guides, or the like.

The term "microfluidic device" refers to a device having features of micrometer or submicrometer dimensions, and which can be used in any number of chemical processes involving very small amounts of fluid. Such processes include, but are not

limited to, electrophoresis (e.g., capillary electrophoresis or CE), chromatography (e.g., μ LC), screening and diagnostics (e.g., using hybridization or other binding means), and chemical and biochemical synthesis (e.g., DNA amplification as may be conducted using the polymerase chain reaction, or "PCR"), and analysis (e.g., through enzymatic digestion). The features of the microfluidic devices are adapted to the particular use intended. For example, microfluidic devices that are used in separation processes such as chromatography contain microchannels (termed herein as "microconduits" when they are enclosed, i.e., when the cover plate is in place on the microchannel-containing substrate surface) on the order of 1 μ m to 200 μ m in diameter, typically 10 μ m to 75 μ m in diameter, and approximately 0.1 to 50 cm in length. For microfluidic devices that are used in generating or holding a gradient-containing mobile phase, conduits associated with gradient-generation means may have a volume of about 1 nL to about 100 μ L, typically about 10 nL to 20 μ L.

The term "mobile phase" as used herein refers to any fluid capable of movement under a motive force. Although the term "mobile phase" is typically used in the context of separation processes such as chromatography, the term is not limited to such processes.

"Optional" or "optionally" as used herein means that the subsequently described feature or structure may or may not be present, or that the subsequently described event or circumstance may or may not occur, and that the description includes instances where a particular feature or structure is present and instances where the feature or structure is absent, or instances where the event or circumstance occurs and instances where it does not.

The invention generally relates to a microfluidic device for separating the components of a fluid sample, wherein the microfluidic device is formed from a substrate having a microchannel in a surface thereof and a cover plate arranged over the substrate surface. The cover plate, in combination with the microchannel, defines a separation conduit for separating the components of a fluid sample according to a specific component property; the separation conduit has an inlet port and an outlet port. The microfluidic device also includes an integrated gradient-generation means for generating

a gradient of a selected mobile-phase component in a mobile phase. The integrated gradient-generation means is arranged to allow the mobile phase from the gradient-generation means to be transported through the inlet port into the separation conduit and out of the outlet port. Typically, though not necessarily, the integrated gradient-generation means is formed at least in part within the substrate and/or in the cover plate.

Typically, the integrated gradient-generation means includes a mobile-phase holding conduit having a length defined by an upstream terminus and a downstream terminus. A plurality of inlet ports is arranged along the length of the mobile-phase holding conduit, and an outlet port is located downstream from the inlet ports of the mobile-phase holding conduit. An introduction means is provided for introducing the mobile phase from the mobile-phase holding conduit through its outlet port and into the inlet port of the separation conduit. This gradient-generation means, as well as variations thereof, is further discussed below.

FIG. 1 illustrates an embodiment of the inventive microfluidic device having an integrated gradient-generation means as described above, in combination with a separation column for liquid chromatography. As with all figures referenced herein, in which like parts are referenced by like numerals, FIG. 1 is not necessarily to scale, and certain dimensions may be exaggerated for clarity of presentation. As illustrated in FIG. 1, the microfluidic device **10** includes a substrate **12** comprising first and second substantially planar opposing surfaces indicated at **14** and **16**, respectively, and is comprised of a material that is substantially inert with respect to fluids that will be transported through the microfluidic device. The substrate **12** has a first fluid-transporting feature in the form of a separation microchannel **18** and a second fluid-transporting feature in the form of a mobile-phase holding microchannel **20**, each microchannel located in the first planar surface **14**. The separation microchannel **18** represents a portion of a separation conduit **19**, and the mobile-phase holding microchannel **20** represents a portion of the mobile-phase holding conduit **21**, as discussed below. The separation microchannel **18** has a sample inlet terminus **24** at an upstream end and a sample outlet terminus **26** at the opposing end. As shown in FIG. 1, the sample outlet terminus **26** is located at a protrusion of the otherwise rectangular

substrate **12**. Similarly, the mobile-phase holding microchannel **20** has a length defined by an upstream terminus **28** and a downstream terminus **30**.

The substrate **12** has six conduits, indicated at **17A**, **17B**, **17C**, **17D**, **17E** and **17F** that extend through surfaces **14** and **16** and that represent the vertices of an equilateral hexagon. Conduit **17A** is located at the downstream terminus **30** of the mobile-phase holding microchannel **20**. Conduit **17B** is located at the sample inlet terminus **28** of the separation microchannel **18**.

The microfluidic device **10** also includes a cover plate **40** that is complementarily shaped with respect to the substrate **12** and has first and second substantially planar opposing surfaces indicated at **42** and **44**, respectively. The cover plate **40** can be comprised of any suitable material for forming the substrate **12** as described below. The contact surface **42** of the cover plate **40** is capable of interfacing closely with the contact surface **14** of the substrate **12** to achieve fluid-tight contact between the surfaces. The cover plate **40** may include a variety of features. As shown, mobile-phase inlet ports **48** and **50** are provided as a cylindrical conduit extending through the cover plate **40** in a direction orthogonal to the cover plate contact surface **42** to result in fluid communication between surfaces **42** and **44**. Similarly, sample inlet port **72** and sample outlet port **46** are provided as conduits extending from surface **42** to surface **44**. A sample introduction channel **66** having termini **68** and **70** is located on contact surface **42**.

The cover plate **40** is substantially immobilized over the substrate contact surface **14**, and the cover plate contact surface **42** in combination with the separation microchannel **18** defines a sample conduit **19** for conveying the sample. Similarly, the cover plate **40**, in combination with the mobile-phase holding channel **20**, defines a mobile-phase holding conduit **21**. In addition, the sample introduction channel **66** combined with the substrate contact surface **14** forms sample introduction conduit **67**. Because the contact surfaces of the cover plate and the substrate are in fluid-tight contact, the separation conduit **19**, the mobile-phase holding conduit **21**, and sample introduction conduit **67** are all fluid-tight as well. Mobile-phase inlet port **48** is located over the upstream terminus **28** of the mobile-phase holding-channel **20** and mobile phase inlet port **50** is located over the mobile-phase holding channel **20** at approximately the midpoint

between its termini **28** and **30**. Sample inlet port **72** and sample outlet port **46** are aligned with conduits **17E** and **17D**, respectively. Termini **68** and **70** of sample introduction channel **66** are aligned with conduits **17F** and **17C**, respectively.

A switching plate **60** is provided as an integrated means for sample introduction.

The switching plate also serves to provide controllable communication between the mobile-phase holding conduit **21**, the sample introduction conduit **67**, and the separation conduit **19**. This switching plate **60** is similar to that described in U.S. Serial Nos. 09/908,292 and 09/908,231. As depicted in FIG. 1A, the switching plate **60** has a substantially planar and circular contact surface **62** and an opposing surface **64**. As shown, the surfaces **62** and **64** are generally congruent. Three curved fluid-transporting channels, indicated at **74A**, **74B** and **74C**, are each located on contact surface **62**. The three fluid-transporting channels lie along a circle having a diameter equal to the length of sample introduction channel **66**. Each fluid-transporting channel has two termini such that each terminus represents a vertex of an equilateral hexagon that is congruent with the equilateral hexagon formed by the through conduits **17A-17F** of the substrate **12**. The switching plate contact surface **62** may be placed in slidable and fluid-tight contact with substrate surface **16**. As a result, the fluid-transporting channels, **74A**, **74B**, and **74C**, in combination with substrate surface **16**, form three curved conduits, **75A**, **75B**, and **75C**, respectively.

Depending on the relative orientation of the switching plate and the substrate two possible flow paths configurations can be created. As shown in FIG. 1B, the first flow path configuration allows a sample fluid to be introduced into the microfluidic device through sample inlet port **72** through conduit **75C**, the sample introduction conduit **67** and conduit **75B**. The sample fluid may then exit the microfluidic device **10** through sample outlet port **46**. By rotating the switching plate **60** 60° about its center, a second flow path configuration results, as shown in FIG. 1C. The second flow path configuration positions the sample introduction conduit **67** in a flow path between the mobile-phase holding conduit **21** and the separation conduit **19**. As a result, a flow path is formed from mobile-phase holding conduit **21** through conduit **75C**, sample introduction conduit **67**, conduit **75A**, and separation conduit **19**.

10010924-1
REED & ASSOC.
PATENT

The microfluidic device may be employed in a method for separating the components of a fluid sample in a manner similar to that of a simple capillary liquid chromatographic apparatus. The integrated gradient-generation means may be used to generate the gradient of the selected mobile-phase component in the mobile phase by providing the inlet ports **48** and **50** of the mobile-phase holding conduit fluid communication with a source of mobile phase (not shown) such that mobile phase containing differing concentrations of the selected mobile-phase component may be introduced into each inlet port. Thus, once filled with mobile phases from the inlet ports **48** and **50**, the upstream portion of the mobile-phase holding conduit **21** may contain a different concentration of the selected mobile-phase component than the downstream portion. Given sufficient time for diffusion to occur, the mobile-phase holding conduit **21** along its length may contain mobile phase that exhibits a smooth gradient of the selected mobile-phase component. By proper choice of the concentration of the selected mobile-phase component in a mobile-phase source, the gradient of the selected mobile-phase component may increase or decrease along the length of the mobile-phase holding conduit **21** in a downstream direction.

In addition, as shown in FIG. 1B, fluid sample is introduced into the sample inlet port **72** to fill the sample introduction conduit **67**. Typically, the combination of the sample introduction conduit **67** and conduit **75C** holds a predetermined volume (i.e., a plug) of sample therein. Once a desired gradient is formed in the mobile-phase holding conduit **21**, the switching plate **60**, as indicated in FIG. 1C is slidably rotated to provide communication between the mobile-phase holding conduit **21** and the separation conduit **19**. A pressurizing means (not shown) provides a motive force to deliver the mobile phase contained in the mobile-phase holding conduit **21** through the sample introduction conduit **67** and into the separation conduit **19**. As a result, the fluid sample contained within the sample introduction conduit **67** is conveyed though the separation conduit **19**. Typically, separation within the separation conduit **19** is carried out using a mobile-phase flow rate of no more than about 1 $\mu\text{L}/\text{min}$. However, flow rates of about 0.01 $\mu\text{L}/\text{min}$ to about 10 $\mu\text{L}/\text{min}$ may be employed, with flow rates of about 0.1 $\mu\text{L}/\text{min}$ to about 2 $\mu\text{L}/\text{min}$ preferred. The fluid sample is then separated into sample components according

to a specific component property and emerges from an outlet port **47** at the terminus **26** of the separation conduit. The outlet port **47** may be interfaced with a collector, such as a sample vial, plate, or capillary. The collector may serve as a storage device or represent an intermediary to another device that uses and/or analyzes collected sample fractions.

5 Alternatively, an analytical device such as a mass spectrometer may be directly or indirectly interfaced with the outlet port **47** for fraction analysis.

Although a plurality of inlet ports is depicted as arranged along the length of the mobile-phase holding conduit in FIG. 1, this configuration is not a necessity. FIG. 2 illustrates another version of the inventive microfluidic device **10**, similar to that depicted in FIG. 1 except that the mobile-phase holding conduit **21** of the integrated gradient-generation means has a single inlet port **48** located at its upstream terminus rather than a plurality of inlet ports arranged along the length of the mobile-phase holding conduit. In addition, the integrated gradient-generation means includes an additional switching plate **80** that contains a mobile-phase introduction conduit **82** to provide the mobile-phase holding conduit **21** with alternating fluid communication with a plurality of mobile-phase sources indicated at **49** and **51**, and each source containing a different concentration of the selected mobile-phase component for gradient formation. As shown in FIG. 2A, a first mobile-phase source **49** is provided fluid communication through the mobile-phase introduction conduit **82** with the mobile-phase holding conduit **21** of the microfluidic device **10**, while a second mobile-phase source **51** is fluidly isolated from the mobile-phase holding conduit **21**. FIG. 2B illustrates that the second mobile-phase source **51** may be provided fluid communication with the mobile-phase holding conduit **21** through the mobile-phase introduction conduit **82** while the first mobile-phase source **49** is fluidly isolated from the mobile-phase holding conduit **21**.

25 By providing the mobile-phase holding conduit **21** with alternating fluid communication in a predetermined loading sequence with mobile-phase sources **49** and **51**, the mobile-phase holding conduit **21** may be filled with a mobile phase having a concentration profile of the selected mobile-phase component along the length of the mobile-phase holding conduit **21**. As before, given sufficient time for diffusion to occur, the mobile phase along the length of the mobile-phase holding conduit **21** may come to

contain a smooth gradient of the selected mobile-phase component. For example, the first mobile-phase source **49** may contain the selected mobile-phase component in a pure form, and the second mobile-phase source **51** may contain a fluid that does not contain the selected mobile-phase component. Plugs of increasing volume of fluid from the first mobile-phase source **49** are alternatingly introduced through inlet port **48** into the mobile-phase holding conduit **21** with plugs of identical volumes of fluid from the second mobile-phase source **51**. Such alternating introduction can be effected through a number of valve actuation technologies including those that employ computer-aided control.

In another embodiment, the invention relates to a microfluidic device for separating the components of a fluid sample. The microfluidic device comprises a gradient-generation means, a separation conduit for separating the components of a fluid sample according to a specific component property, as well as a means for introducing mobile phase from the gradient-generation means. The gradient-generation means is constructed from a substrate and a cover plate. A microchannel is formed in a surface of the substrate and has an upstream terminus and a downstream terminus. The cover plate is arranged over the substrate surface and, in combination with the microchannel, forms a mobile-phase holding conduit having a length defined by the upstream terminus and the downstream terminus. A plurality of inlet ports is arranged along the length of the mobile-phase holding conduit, and an outlet port is located downstream from the inlet ports of the mobile-phase holding conduit. Each of the inlet ports may fluidly communicate with the same or different sources of mobile phase as described below.

Generally, increasing the number of inlet ports for the mobile-phase holding conduit will provide greater control in gradient generation. Thus, the mobile-phase holding conduit may have any number of inlet ports greater than two. It is generally

preferred that the inlet ports be evenly spaced along the length of the mobile-phase holding conduit, particularly when the mobile-phase holding conduit represents a gradient-generation means that comprises a cascade of conduits that split and mix streams of liquids (for example, water and methanol). A similar cascade is generally described in Whitesides et al. (2001), "Flexible Methods for Microfluidics," *Physics Today* 52(6):42-47. As described in Whitesides et al., the cascade may be employed in techniques that involve the immobilization of cells in a pattern on a surface of a microfluidic device wherein the cells are exposed to fluids containing appropriate reagents. Splitting of streams of liquid occurs at T-junctions between mixing channels and distribution channels. At steady state, the ultimate result of this splitting and mixing is the generation of a stepwise concentration gradient. However, the fluids may be delivered as a linear gradient of an appropriate reagent, e.g., a dye gradient, formed by diffuse mixing through a network of microchannels.

FIG. 3 illustrates an example of such a cascade on a microfluidic device **10** similar to that illustrated in FIG. 1. The cascade is depicted as a collection of microconduits formed from the combination of microchannels on a substrate and a cover plate, although this is not a necessity. The gradient-generation means includes a mobile-phase holding conduit **21** having an upstream terminus **28** and a downstream terminus **30**. Five inlet ports, indicated at **48A**, **48B**, **48C**, **48D**, and **48E**, are evenly spaced along its length. An outlet port **52** is located at the downstream terminus **30**. As shown, no inlet port is located at either terminus of the mobile-phase holding conduit. Three distribution conduits, indicated at **90**, **100**, and **110**, are arranged in parallel disposition in successively increasing distances to the mobile-phase holding conduit **21**. Each successive distribution conduit from the mobile-phase holding conduit **21** has the same number of outlet ports as the preceding conduit. However, each successive distribution conduit from the mobile-phase holding conduit **21** has one fewer inlet port than the preceding conduit. Thus, distribution conduit **90** has five outlet ports **91A**, **91B**, **91C**, **91D**, and **91E**, and four inlet ports **92A**, **92B**, **92C**, and **92D**; distribution conduit **100** has four outlet ports **101A**, **101B**, **101C**, and **101D**, and three inlet ports **102A**, **102B**, and **102C**; and distribution conduit **110** has three outlet ports **111A**, **111B**, and **111C**, and two

inlet ports **112A** and **112B**. Each outlet port of each distribution conduit fluidly communicates via a mixing conduit with an inlet port of a successive conduit. Each inlet port of the distribution conduits is located between two outlet ports of the same distribution conduit.

5 The gradient-generation process is now described. Turning to distribution conduit **110**, inlet ports **112A** and **112B** are provided fluid communication with two sources of mobile phase, each holding a different concentration of the selected mobile-phase component for which a gradient is to be generated. Typically, one of the mobile-phase sources (in this case, the mobile-phase source communicating with inlet port **112A**, holds a first mobile phase of the selected mobile-phase component while the other mobile-phase source (in this case, the mobile-phase source communicating with inlet port **112B** holds a second mobile phase that contains another selected mobile-phase component altogether. When mobile phases from the mobile-phase sources are introduced into distribution conduit **110**, the first and second mobile phases will preferentially fill the portion of the conduit closest to their associated inlet ports. Thus, the first mobile phase will preferentially fill the portion of distribution conduit **110** closer to outlet port **111A**, and the second mobile phase will preferentially fill the portion of the distribution conduit **110** closer to terminus **111C**. Mixing channel **115A** will contain only the first mobile phase, and mixing channel **115C** will contain only the second mobile phase.

10 However, as mixing channel **115B** lies between inlet ports **112A** and **112B**, mixing channel **115B** will contain both mobile phases. Thus, the inlets along distribution conduit **100** will provide mobile phases containing increasing concentrations the selected mobile phase along the length of the distribution conduit from outlet **101A** to outlet **101D**. It should be evident that this mixing and redistribution process is repeated for 15 each of the distribution conduits to result in the generation of a smooth gradient in the mobile-phase holding conduit **21**. Optionally, a plurality of waste/exhaust ports indicated at **121** is provided in fluid communication with mobile-phase holding conduit to allow any air or other fluid contained in the mobile-phase holding conduit to be displaced during the gradient generation process. As shown, the waste/exhaust ports may fluidly communicate with each other through converging conduits **123** at gradient outlet **125**.

Once a gradient is generated in the mobile-phase holding conduit 21, a pressurizing means (not shown) may be employed to provide a motive force to deliver the mobile phase contained in the mobile-phase holding conduit into the separation conduit 19 to carry out separation processes as described above and elsewhere herein.

In order to ensure the proper formation of a smooth gradient, the following considerations should be addressed. First, the residence time of the fluids in the mixing conduits should be sufficiently long to ensure near-complete mixing. Second, the flow resistance of the mixing conduits should be significantly greater than the flow resistance of the distribution and holding conduits. This minimizes backflow into the mixing conduits as the concentration gradient is pumped out of the holding conduit. Third, the characteristic length of the cascade should be long enough to prevent destruction of the gradient by complete diffuse mixing while it is waiting to be pumped into the separations. However, as discussed above, some degree of diffusion may be beneficial in smoothing of the concentration steps. Finally, additional design considerations, such as tailoring of the dimensions of each individual mixing conduit, can be made to account for differences in viscosity between the two mobile phases. Although mobile phases having different viscosities may be used, the following analyses assume that the mobile phases have the same viscosity and that the conduits are formed from conduits.

With respect to residence time, a two-dimensional order of magnitude analysis assuming a uniform flow with no entrance length effects and no reflections at the conduit, yields the following dependence for the characteristic mixing length, L_m :

$$L_m \sim a^2 \bar{u} / 2D = a \cdot Pe / 2 \quad (1)$$

where a is the half-width of the conduit, \bar{u} is the average flow velocity in the conduit, D is the diffusion coefficient of the diffusing species, and Pe is the Peclet number (which expresses the ratio of convective to diffusive transport).

The gradient-generation cascade is designed such that the flow resistance of the mixing conduits is much greater than the flow resistance of the distribution and holding conduits. In this case, the flow resistance of the distribution conduits can be neglected,

resulting in an equal distribution of the total volumetric flow rate, Q , among the mixing conduits. Each mixing conduit would then support a flow rate equal to the total flow rate, Q , divided by the number of conduits in that stage of the cascade. Thus, the highest flow rates are encountered at the first mixing conduits, resulting in the following order of magnitude estimate for the characteristic mixing length of conduits with a cross-sectional area given by $2a * h$ (twice the half-width, multiplied by the depth of the conduit):

$$L_m \sim aQ/12Dh \quad (2)$$

Then, for example, the characteristic mixing length for a species with a diffusion coefficient of $1.28 \times 10^{-5} \text{ cm}^2/\text{s}$, a conduit with a depth $h = a$, and a total volumetric flow rate of 300 nL/min , would be on the order of $330 \mu\text{m}$. In summary, the mixing conduits should be at least three times the characteristic mixing length, which is directly proportional to the total volumetric flow rate and inversely proportional to the product of the diffusion coefficient and the aspect ratio, h/a , of the conduit. For a given diffusing species, we can reduce the mixing length by lowering the total flow rate and aspect ratio of the conduit.

A more detailed analytical solution for the two-dimensional problem, including wall reflections, is given in Jeon et al. (2000), "Generation of solution and surface gradients using microfluidic systems," *Langmuir* 16:8311-8316; and in Crank, *The Mathematics of Diffusion*, 2nd Ed., Oxford University Press, Oxford, 1975, pp. 16. The Netflow Module of FlumeCAD (Coventor, Inc., Cary, NC) has also been employed to calculate the mixing length for the conditions listed above. According to these simulations, near-complete mixing occurs at approximately 1000 mm into the conduit, or approximately three characteristic mixing lengths away from the entrance to the conduit.

With respect to the flow resistance of the mixing conduits in relationship to the flow resistance of the distribution and holding conduits, the equivalent flow resistance of a flow conduit supporting fully developed laminar flow can be approximated by:

$$R = |\Delta p/Q| = 128\mu L/\pi d_h^4 \quad (3)$$

where Δp is the change in pressure, μ is the viscosity of the fluid, L is the length of the conduit, and d_h is the hydraulic diameter of the conduit. The hydraulic diameter is defined as four times the cross-sectional area of the conduit, divided by the perimeter of the cross section. The depth, h , of a shallow conduit dominates in the computation of the hydraulic diameter.

The requirement that the flow resistance of the mixing conduits be much greater than the flow resistance of the distribution and holding conduits can be expressed as:

$$(d_h)_{\text{dist}}^4/L_{\text{dist}} \gg (d_h)_{\text{mix}}^4/L_{\text{mix}} \quad (4)$$

The characteristic length of the cascade, A, and the diffusion coefficient of the diffusing species are the parameters that determine the stability of the gradient in the holding conduit as the gradient is waiting to be introduced into the separation conduit. From a simulation of the concentration of water and methanol in the holding conduit as a function of time for a conduit 200 μm wide, a characteristic length of 5000 μm , and nine gradient steps (i.e., a gradient cascade of order 9), a smooth gradient is formed after about one minute and is stable for at least 50 minutes.

Thus, the invention also relates to a microfluidic device having an integrated mobile-phase source. The microfluidic device comprises a substrate having a microchannel formed in a surface thereof and a cover plate arranged over the substrate surface. The cover plate in combination with the microchannel defines a separation conduit for separating the components of a fluid sample according to a specific component property and has an inlet port and an outlet port. An integrated mobile-phase source is provided, which comprises a microconduit having a length defined by an

upstream terminus and a downstream terminus. The microconduit contains a mobile phase that exhibits a gradient of a selected mobile-phase component along the length of the microconduit. The integrated mobile-phase source is arranged to allow the mobile phase to be transported through the inlet port into the separation conduit and out of the outlet port.

Through proper microfluidic device design and construction, it is now possible to use no more than about 100 μL of fluid to produce a mobile phase containing a gradient of the selected mobile-phase component to carry out gradient chromatography.

Preferably, no more than about 50 μL of fluid is used to produce the gradient-containing mobile phase. Optimally, no more than about 10 μL of fluid is used to produce the gradient-containing mobile phase. The gradient-containing mobile phase is used to convey a fluid sample through the separation conduit, thereby separating the components of the fluid sample.

From the above, it is evident that the invention, in addition to providing a device for separating the components of a fluid, also provides a microfluidic device for producing a flow of mobile phase. The device comprises a mobile-phase source and a pressurizing means. The mobile-phase source comprises a mobile-phase holding microconduit having a length defined by an upstream terminus and a downstream terminus, and an outlet port located at the downstream terminus, and a mobile phase, contained in the mobile-phase holding microconduit, that exhibits differing concentrations of selected mobile-phase component along the length of the mobile-phase holding microconduit. The pressurizing means allows for the pressurization of the microconduit to force the mobile phase within the microconduit to flow toward the downstream terminus along the length of the microconduit and out the outlet port. Any number of pressurizing means known in the art may be used and include, for example, syringes, pumps, pressurized gases, etc. Although electrokinetic forces may be used as well, they are not preferred. Such forces are dependent on the concentration of the mobile phase and the electrokinetic mobility will vary along any flow path exhibiting a gradient, leading to difficulties in control over mobile phase movement.

The mobile-phase as described above, may be produced by any of a number of

different techniques, described herein with references to FIGS. 1-3, in the context of chemical separation using a gradient-containing mobile phase. However, mobile phases may also be employed in the context of fields other than chemical separation. In addition, it should be apparent the gradient-generation means as described above may be adapted to produce a mobile phase that contains different concentrations of a selected mobile-phase component at different locations within a mobile phase.

Thus, the invention also generally relates to a microfluidic device for producing a flow of mobile phase, wherein a producing means is provided to generate a gradient of a selected mobile-phase component in a mobile phase, to produce a mobile phase exhibiting different concentration of a selected mobile-phase component in different locations within the mobile phase, or both. Such a producing means typically comprises a mobile-phase-holding microconduit having a length defined by an upstream terminus and a downstream terminus, an outlet port located at the downstream terminus, and at least one inlet port in fluid communication with the mobile-phase holding microconduit upstream from the outlet port. A plurality of mobile-phase sources are also provided, wherein each source contains a mobile phase having a different concentration of a selected mobile-phase component. An introduction means introduces plugs of mobile phase from the mobile-phase sources through the at least one inlet port into the mobile-phase holding conduit such that the plugs are arranged in a predetermined order along the length of the mobile-phase holding conduit. As illustrated in FIG. 2, the introduction means may be formed at least in part by a switching structure.

FIGS. 4 and 5 illustrate two additional switching structures that may be employed as an introduction means. FIG 4 illustrates a microfluidic switching structure similar to that described in U.S. Serial No. 09/908,231. The switching structure employs rotational motion to controllably introduce a plug of a mobile phase. As illustrated in FIG. 4A, the switching structure 10 includes a substrate 12 comprising first and second substantially planar opposing surfaces indicated at 14 and 16, respectively. The substrate 12 has six conduits, indicated at 17A, 17B, 17C, 17D, 17E and 17F that extend through surfaces 14 and 16 and that represent the vertices of an equilateral hexagon.

The switching structure **10** also includes a cover plate **40** that is complementarily shaped with respect to the substrate **12** and has first and second substantially planar opposing surfaces indicated at **42** and **44**, respectively. The contact surface **42** of the cover plate **40** is capable of interfacing closely with the contact surface **14** of the substrate **12** to achieve fluid-tight contact between the surfaces. The cover plate **40** is substantially immobilized over the substrate contact surface **14**. The cover plate **40** includes a variety of features. As shown, a first cover plate conduit **48A** is provided extending through the cover plate in a direction orthogonal to the cover plate contact surface **42** to provide communication between surfaces **42** and **44**. The first cover plate conduit **48A** is arranged to communicate with the conduit **17A** of the substrate **12** and enables passage of first mobile phase from a first mobile phase source (not shown) through conduit **17A** to communicate with switching plate **120** as discussed below. Two additional cylindrical conduits, indicated at **53A** and **48B** are provided fluid communication with conduits **17F** and **17C**, respectively.

A linear channel **53B** having two termini, indicated at **53C** and **53D**, is located in contact surface **42**. The termini **53C** and **53D** fluidly communicate with conduits **17E** and **17B**, respectively. The termini **53C** and **53D** in combination with conduits **48A**, **48B** and **53A** represent five of six vertices of an equilateral hexagon. Accordingly, each of the conduits is located the same distance from the center point of the channel **53B**. As discussed above, the cover plate **40** is substantially immobilized over the substrate contact surface **14**. As a result, substrate surface **14** in combination with channel **53B** forms a conduit **55**, which serves as a plug holding chamber, discussed below. Alternatively, the linear channel **53B** may be provided on substrate surface **14**. In such a case, termini **53C** and **53D** would coincide in location with conduits **17B** and **17E**, respectively.

As shown in FIG. 4A, the switching plate **120** has a substantially planar and circular contact surface **122** and an opposing surface **124**. Three curved fluid-transporting channels, indicated at **126**, **128** and **130**, are each located on contact surface **122**. The three fluid-transporting channels lie along a circle having a diameter equal to the length of channel **53B**. Each fluid-transporting channel has two termini: termini

A D D E S S O R - C A P T U R E

5

10

15

30

126A and 126B are associated with channel 126, termini 128A and 128B are associated with channel 128, and termini 130A and 130B are associated with channel 130. The switching plate contact surface 122 may be placed in slidable and fluid-tight contact with substrate surface 16. As a result, the fluid-transporting channels, 126, 128 and 130, in combination with substrate surface 16, form three curved conduits, 126C, 128C, 130C, respectively.

Depending on the relative orientation of the switching plate and the substrate, at least two possible flow paths configurations can be created. As shown in FIG. 4B, the first flow path configuration allows a first mobile phase from a first mobile-phase source to travel, in order, through conduit 48A, conduit 17A, conduit 126C, conduit 17B, conduit 55, conduit 17E, conduit 128C, conduit 17F and conduit 53A. The first flow path configuration also allows a second mobile phase from a second mobile-phase source (not shown) to travel, in order, through conduit 48B, conduit 17C, conduit 130C, and conduit 17D. Typically, the first and second mobile-phase sources contain differing concentrations of a mobile phase component. By rotating the switching plate 120 60° about its center, a second flow path configuration results, as shown in FIG. 4C. The second flow path configuration allows the first mobile phase to travel, in order, through conduit 48A, conduit 17A, conduit 126C, conduit 17F, and conduit 453A. In addition, the second flow path configuration allows the second mobile phase to travel, in order, through conduit 48B, conduit 17C, conduit 130C, conduit 17B, conduit 55, conduit 17E, conduit 128C and conduit 17D.

In use, the switching plate 120 of the switching structure is arranged to result in a first flow path configuration as discussed above. A pressurizing means deliver a second mobile phase from a second mobile-phase source through mobile phase inlet conduit 48B, conduit 17C, conduit 130C, and conduit 17D. In addition, a first mobile phase is conveyed from the first mobile-phase source through conduit 48A. As a result, the first mobile phase forms a contiguous body of fluid that flows, through conduit 48A, conduit 17A, conduit 126C, conduit 17B, conduit 55, conduit 17E, conduit 128C, conduit 17F and conduit 53A. The mobile phase emerging from conduit 53A may be collected and recycled. Thus, conduit 55 is filled with a plug of the first mobile phase.

By forming a second flow path configuration as discussed above, the conduit **55** is now positioned in the flow path of the mobile phase entering the switching structure through conduit **48B**. That is, the second mobile phase is now pumped through a flow path that travels, in order, through conduit **48B**, conduit **17C**, conduit **130C**, conduit **17B**, 5 conduit **55**, conduit **17E**, conduit **128C** and conduit **17D**. Thus, the first mobile phase within conduit **55** is also forced through conduit **17D**. It should be evident, then, that by rotating the substrate of the switching assembly, a first mobile-phase plug having a volume defined by conduit **55** is controllably introduced from a first mobile-phase source through conduit **17D** followed by a second mobile phase. By providing fluid 10 communication between conduit **17D** and an inlet of a mobile-phase holding conduit (not shown), the mobile-phase holding conduit may be filled with a mobile phase that contains a first mobile-phase plug downstream from a second mobile-phase plug, thereby forming an overall mobile phase, contained in the mobile-phase holding conduit, that exhibits differing concentrations of a mobile phase component.

FIG. 5, illustrate a switching structure that employs rotational motion to 15 controllably introduce plug of a first mobile phase, followed by, in order, a plug of a second mobile phase and the first mobile phase through a conduit. Like the switching structure illustrated in FIG. 4, the switching structure illustrated in FIG. 5 also employs rotational motion to controllably introduce a plug of a mobile phase. The switching structure **10** includes a substrate **12** and a switching plate **120** each having contact surface 20 in slidable and fluid-tight relationship with each other. Eight conduits indicated at **17A**, **17B**, **17C**, **17D**, **17E**, **17F**, **17G** and **17H**, extend through the substrate and represent the vertices of an equilateral octagon.

The contact surface of the switching plate has located thereon four curved fluid- 25 transporting channels. The four fluid-transporting channels lie along a circle having a diameter equal to the distance between two substrate conduits located farthest from each other. As a result, the fluid-transporting channels, in combination with substrate contact surface, form four conduits, **126C**, **128C**, **130C** and **132C**, as shown in FIG. 5.

Furthermore, two microconduits, indicated at **134** and **136**, are provided as plug- 30 holding chambers. Microconduit **134** provides fluid communication between substrate

conduits **17B** and **17D**, and microconduit **136** provides fluid communication between substrate conduits **17E** and **17H**. Such microconduits may comprise, for example, commercially available capillary tubing. Depending on the relative orientation of the switching plate and the substrate, at least two possible flow paths configurations can be created. As shown in FIG. 5A, the first flow path configuration allows a first mobile phase from a first mobile-phase source (not shown) to travel, in order, through conduit **17A**, conduit **126C**, conduit **17B**, conduit **134**, conduit **17D**, conduit **128C** and conduit **17C**. The first flow path configuration also allows a second mobile phase from a second mobile-phase source (not shown) to travel, in order, through conduit **17G**, conduit **132C**, conduit **17H**, conduit **136**, conduit **17E**, conduit **130C**, and conduit **17F**. This configuration allows plug-holding chamber **134** to be filled by the first mobile phase and plug holding chamber **136** to be filled by the second mobile. By rotating the switching plate **120** 45° about its center, a second flow path configuration results, as shown in FIG. 5B. The second flow path configuration forms a first flow path extending, in order, through conduit **17A**, conduit **126C**, conduit **17H**, conduit **136**, and conduit **17E**, conduit **130C**, conduit **17D**, conduit **134**, conduit **17B**, conduit **128C** and conduit **17C**. The second flow path configuration also forms a second flow path extending, in order, through conduit **17G**, conduit **132C**, and conduit **17F**. Thus, by rotating the substrate of the switching assembly, a first mobile-phase plug defined by conduit **134** is introduced through conduit **17C** followed by a second mobile-phase plug defined by conduit **136**, which is followed by additional first mobile phase. By providing fluid communication between conduit **17C** and an inlet of a mobile-phase holding conduit (not shown), the mobile-phase holding conduit may be filled with a mobile phase that contains a first mobile-phase plug downstream from a second mobile-phase plug, which is downstream from an additional first mobile-phase plug, thereby forming an overall mobile phase, contained in the mobile-phase holding conduit, that exhibits differing concentrations of a mobile phase component.

Thus, the invention provides, in yet another embodiment, a method for producing a flow of mobile phase. A mobile-phase source is provided comprising a mobile-phase-holding microconduit having a length defined by an upstream terminus and a downstream

terminus, and an outlet port located at the downstream terminus, and a mobile phase, contained in the mobile-phase holding microconduit, that exhibits differing concentrations of selected mobile-phase component along the length of the microconduit a substrate. The mobile-phase holding microconduit is pressurized to force the mobile phase within the mobile-phase holding microconduit to flow toward the downstream terminus along the length of the microconduit and out of the outlet port. Optionally, at least one inlet port is provided fluid communication with the mobile-phase holding microconduit, wherein the outlet port is located downstream from the at least one inlet port of the mobile-phase holding microconduit. In such a case, a plurality of mobile-phase sources may be provided as well, each containing a mobile phase, wherein each mobile phase contains a different concentration of a selected mobile-phase component. Plugs of mobile phase from the mobile-phase sources are introduced through the at least one inlet port into the mobile-phase holding microconduit such that the plugs are arranged in a predetermined order along the length of the mobile-phase holding conduit.

In any of the above embodiments, suitable materials for forming the substrates and cover plates are selected with regard to physical and chemical characteristics that are desirable for proper functioning of the microfluidic device. In all cases, the substrate must be fabricated from a material that enables formation of high definition (or high "resolution") features, i.e., microchannels, chambers, and the like, that are of micrometer or submicrometer dimensions. That is, the material must be capable of microfabrication using, e.g., dry etching, wet etching, laser etching, laser ablation, molding, embossing, or the like, so as to have desired miniature surface features; preferably, the substrate is capable of being microfabricated in such a manner as to form features in, on, and/or through the surface of the substrate. Microstructures can also be formed on the surface of a substrate by adding material thereto. For example, polymer channels can be formed on the surface of a glass substrate using photo-imageable polyimide. In addition, a plurality of pieces or layers may be assembled to result in the formation of a substrate having a feature in, on, and/or through the surface of the substrate. Thus, for example, a substrate having a channel located on a surface thereof may be formed from two layers, a first solid layer affixed to a second layer having a through-hole that in combination with the first

solid layer form the channel. Also, all device materials that are used should be chemically inert and physically stable (e.g., in terms of pH, electric fields, etc.) with respect to any substance with which they come into contact when used to introduce a fluid sample. Suitable materials for forming the present devices include, but are not limited to, polymeric materials, ceramics (including aluminum oxide and the like), glass, metals, composites, and laminates thereof.

Polymeric materials are particularly preferred herein, and will typically be organic polymers that are either homopolymers or copolymers, whether naturally occurring or synthetic, and crosslinked or uncrosslinked. Specific polymers of interest include, but are not limited to, polyimides, polycarbonates, polyesters, polyamides, polyethers, polyurethanes, polyfluorocarbons, polystyrenes, poly(acrylonitrile-butadiene-styrene)(ABS), acrylate and acrylic acid polymers such as polymethyl methacrylate, other substituted and unsubstituted polyolefins, and copolymers thereof. Generally, at least one of the substrate and cover plate comprises a biofouling-resistant polymer when the microfluidic device is employed to transport biological fluids. Polyimide is of particular interest and has proven to be a highly desirable substrate material in a number of contexts. Polyimides are commercially available, e.g., under the tradename Kapton®, (DuPont, Wilmington, DE) and Upilex® (Ube Industries, Ltd., Japan).

Polyetheretherketones (PEEK) also exhibit desirable biofouling-resistant properties.

The devices of the invention may also be fabricated from a "composite," i.e., a composition comprised of unlike materials. The composite may be a block composite, e.g., an A-B-A block composite, an A-B-C block composite, or the like. Alternatively, the composite may be a heterogeneous combination of materials, i.e., in which the materials are distinct separate phases; or it may be a homogeneous combination of unlike materials. As used herein, the term "composite" is used to include a "laminate" composite. A "laminate" refers to a composite material formed from several different bonded layers of identical or different materials. Other preferred composite substrates include polymer laminates, polymer-metal laminates (e.g., polymer coated with copper), ceramic-in-metal composites, or polymer-in-metal composites. One preferred composite material is a polyimide laminate formed from a first layer of polyimide, such as

Kapton®, that has been co-extruded with a second, thin layer of a thermal adhesive form of polyimide known as KJ®, also available from DuPont (Wilmington, Delaware).

The present microfluidic devices can be fabricated using any convenient method, including, but not limited to, micromolding and casting techniques, embossing methods, surface micromachining, and bulk-micromachining. The latter technique involves formation of microstructures by etching directly into a bulk material, typically using wet chemical etching or reactive ion etching ("RIE"). Surface micromachining involves fabrication from films deposited on the surface of a substrate. An exemplary surface micromachining process is known as "LIGA." See, for example, Becker et al. (1986), "Fabrication of Microstructures with High Aspect Ratios and Great Structural Heights by Synchrotron Radiation Lithography Galvanoforming and Plastic Moulding (LIGA Process)," *Microelectronic Engineering* 4(1):35-36; Ehrfeld et al. (1988), "1988 LIGA Process: Sensor Construction Techniques via X-Ray Lithography," *Tech. Digest from IEEE Solid-State Sensor and Actuator Workshop*, Hilton Head, SC; Guckel et al. (1991) *J. Micromech. Microeng.* 1: 135-138. LIGA involves deposition of a relatively thick layer of an X-ray resist on a substrate followed by exposure to high-energy X-ray radiation through an X-ray mask, and removal of the irradiated resist portions using a chemical developer. The LIGA mold so provided can be used to prepare structures having horizontal dimensions--i.e., diameters--on the order of micrometers.

Another technique for preparing the present microfluidic devices is laser ablation. In laser ablation, short pulses of intense ultraviolet light are absorbed in a thin surface layer of material. Preferred pulse energies are greater than about 100 millijoules per square centimeter, and preferred pulse durations are shorter than about 1 microsecond. Under these conditions, the intense ultraviolet light photo-dissociates the chemical bonds in the substrate surface. The absorbed ultraviolet energy is concentrated in such a small volume of material that it rapidly heats the dissociated fragments and ejects them away from the substrate surface. Because these processes occur so quickly, there is no time for heat to propagate to the surrounding material. As a result, the surrounding region is not melted or otherwise damaged, and the perimeter of ablated features can replicate the shape of the incident optical beam with precision on the scale of about one micrometer or

less. Laser ablation will typically involve use of a high-energy photon laser, such as an excimer laser of the F₂, ArF, KrCl, KrF, or XeCl type. However, other ultraviolet light sources with substantially the same optical wavelengths and energy densities may be used as well. Laser ablation techniques are described, for example, by Znotins et al. (1987)

⁵ *Laser Focus Electro Optics*, at pp. 54-70, and in U.S. Patent Nos. 5,291,226 and 5,305,015 to Schantz et al.

The fabrication technique that is used must provide for features of sufficiently high definition, i.e., microscale components, channels, chambers, etc., such that precise "microalignment" of these features is possible, i.e., the features must be capable of precise and accurate alignment, including, for example, the alignment of complementary microchannels with each other, the alignment of projections and mating depressions, the alignment of grooves and mating ridges, and the like.

For any of the inventive devices, the fluid-transporting features may be formed, independently or otherwise, through laser ablation or other techniques discussed below or known in the art. It will be readily appreciated that, although the microchannels have been represented in a generally extended form, microchannels for this and other embodiments can have a variety of configurations, such as a straight, serpentine, spiral, or any tortuous path. Further, the microchannels can be formed in a wide variety of crosssectional channel geometries, including semi-circular, rectangular, rhomboidal, and the like; and the channels can be formed in a wide range of aspect ratios.

In some instances, the substrate and the cover plate may be formed in a single, solid flexible piece. Microfluidic devices having a single-piece substrate and cover plate configuration have been described, e.g., in U.S. Patent Nos. 5,658,413 and 5,882,571, each to Kaltenbach et al. However, the cover plate and substrate of the inventive device are typically formed as discrete components. In such a case, microalignment means described herein or known to one of ordinary skill in the art may be employed to align the cover plate with the substrate. To ensure that the conduit or conduits formed between the substrate and the cover plate are fluid-tight, pressure-sealing techniques may be employed, e.g., by using external means (such as clips, tension springs, or an associated clamp), internal means (such as male and female couplings), or chemical means (e.g.,

adhesive or welding) to hold the pieces together. As with all embodiments described herein, the pressure-sealing techniques may allow the contact surfaces to remain in fluid-tight contact under an internal microfluidic device fluid pressure of up to about 100 megapascals, typically about 0.5 megapascals to about 40 megapascals.

The separation conduit for the inventive device is constructed for separation as generally described in U.S. Serial No. 09/908,231. Aspects of known separation technology may be incorporated in the practice of the present invention. For example, the microfluidic device may further comprise separation media within a separation conduit, or a polymeric material formed *in situ* within the separation conduit. When ordinary liquid chromatography packing material is slurry-packed within the separation conduit, a frit structure, micromachined or otherwise, may be included near or at the sample outlet port. The frit structure serves to ensure that the packing material is not displaced from within the sample conduit when a fluid sample and/or a mobile phase are conveyed through the conduit. In addition, it is preferred that the cross-sectional area of the separation conduit be reduced downstream from the frit structure, particularly if the sample outlet port is a part of an electrospray tip as described, for example, in U.S. Serial No. 09/711,804 ("A Microfluidic device Having an Integrated Protruding Electrospray Emitter and a Method for Producing the Microfluidic device"), inventors Brennen, Yin, and Killeen, filed on November 13, 2000. Alternatively, the separation conduit may exhibit a high surface area-to-volume ratio.

Thus, the conduit may exhibit any micromachined structure appropriate for liquid chromatography. In addition, or in the alternative, the conduit may contain any of a number of known liquid chromatographic packing materials. Such packing materials typically exhibit a surface area of about $100\text{ m}^2/\text{g}$ to about $500\text{ m}^2/\text{g}$. The conduit may be adapted to separate fluid sample components according to molecular weight, polarity, hydrophobicity, or other properties through techniques known to one of ordinary skill in the art (e.g., through proper selection of packing materials).

Similarly, an analyzer may be interfaced with any portion of the flow path of the inventive microfluidic device, including the inlet port. The analyzer may be, for example, a mass spectrometer, in which case the outlet port could be located within or

adapted to deliver fluid sample to an ionization chamber. See U.S. Serial No. 09/711,804 ("A Microfluidic device Having an Integrated Protruding Electrospray Emitter and a Method for Producing the Microfluidic device"), inventors Brennen, Yin, and Killeen, filed on November 13, 2000. In addition, mass spectrometry technologies are well known in the art and may involve, for example, laser desorption and ionization technologies, for which uses in conjunction with microfluidic devices are described in U.S. Patent Nos. 5,705,813 and 5,716,825. In the alternative or in addition, the analyzer may be a source of electromagnetic radiation configured to generate electromagnetic radiation of a predetermined wavelength. Depending on the intrinsic properties of the fluid sample and/or any molecular labels used, the radiation may be ultraviolet, visible, or infrared radiation.

From the above description of the various embodiments of the invention, it is evident that a sample-introducing means appropriate to the desired separation process and the dimensions of the microfluidic device may be used to introduce a predetermined volume of fluid sample. Typically, the predetermined volume is less than about 5 μ L. Preferably, the predetermined volume is about 0.005 μ L to about 1 μ L. Optimally, the predetermined volume is about 0.01 μ L to about 0.1 μ L. Examples of sample-introducing means are described in U.S. Serial Nos. 09/908,231 and 09/908,292. Additional sample-introducing means include, but are not limited to, syringes, micropipettes, inkjet printheads, sippers, and other devices known in the art.

Variations of the invention, not explicitly disclosed herein, will be apparent to those of ordinary skill in the art. Other features may be included to carry out known reactions and processes, for example, reactions and processes associated with sample preparation, synthesis, and analysis. Such features may be formed from conduits and channels that provide for fluid flow in a parallel or a nonparallel direction with respect to the contact surfaces. Moreover, cascades may be formed as channels on a single substrate surface, as features on a switching mechanism, or as an assembly of conduits formed as a distinct and separate from the separation column. In addition, one of ordinary skill may adapt the structures and the components of structures discussed above to operate in combination, optionally with other microfluidic flow control mechanisms.

In addition to the use of diffusion to create a gradient, micromixers known the art may be incorporated to accelerate mixing.

It is to be understood that, while the invention has been described in conjunction with the preferred specific embodiments thereof, the foregoing description is intended to illustrate and not limit the scope of the invention. Other aspects, advantages, and modifications within the scope of the invention will be apparent to those skilled in the art to which the invention pertains.

All patents, patent applications, and publications mentioned herein are hereby incorporated by reference in their entireties.
